Player-Tracking Technology: Half-Full or Half-Empty Glass?

Martin Buchheit and Ben Michael Simpson

With the ongoing development of microtechnology, player tracking has become one of the most important components of load monitoring in team sports. The 3 main objectives of player tracking are better understanding of practice (provide an objective, a posteriori evaluation of external load and locomotor demands of any given session or match), optimization of training-load patterns at the team level, and decision making on individual players’ training programs to improve performance and prevent injuries (eg, top-up training vs unloading sequences, return-to-play progression). This paper discusses the basics of a simple tracking approach and the need to integrate multiple systems. The limitations of some of the most used variables in the field (including metabolic-power measures) are debated, and innovative and potentially new powerful variables are presented. The foundations of a successful player-monitoring system are probably laid on the pitch first, in the way practitioners collect their own tracking data, given the limitations of each variable, and how they report and use all this information, rather than in the technology and the variables per se. Overall, the decision to use any tracking technology or new variable should always be considered with a cost/benefit approach (ie, cost, ease of use, portability, manpower/ability to affect the training program).

Keywords: global positioning system, semiautomatic video, inertial sensors, accelerometers, load monitoring

Integrating Various Systems

While the precise analysis of each training sequence (drill database) is of infinite value for improved training prescription and programming both at the individual and team level, the simple monitoring of players overall external (locomotor) load is probably one of the most important aspects of any monitoring system. There has been growing evidence to suggest that tracking overall training load accumulation during preseason and/or its acute changes over the time (spikes in load, referring to the so-called training-stress balance or acute-to-chronic load ratio) may be key in better understanding injury risk. Using the example of soccer (Figure 1), it is not unusual for some players to be tracked by 2 or 3 different systems during the same week. This is likely related to the fact that GPS units, local positioning systems, or radio-frequency-identification sensors are often worn during training sessions, while most teams still use semiautomatic camera systems during official matches. Since a perfect between-systems agreement in terms of locomotor activity (eg, distance covered, number of accelerations) is problematic, simply providing a cumulative summation of the data gathered by the different systems is highly hazardous. To allow a proper evaluation of a player’s overall locomotor load, and to integrate accordingly the data of different systems, practitioners are recommended to use calibration equations. Such equations are meant to predict, for example, the running distance that would have been measured with a given system (eg, GPS), while it was actually measured with another one (eg, semiautomatic cameras during a match). While such equations are sometimes provided in the literature from large-scale studies with players tracked simultaneously using different systems under different conditions (eg, training, matches over different pitch sizes), their usefulness is somewhat limited to the actual systems used to derive those equations; it is therefore advised that practitioners develop their equations using their own systems. It is also important that practitioners readjust these equations when updates in their technology occur. The most relevant variables to integrate will be discussed in the following section.
Considering that the ideal system does not exist yet, and that all systems have their own advantages and disadvantages, while still all providing more or less the same variables,\textsuperscript{5} it may be more relevant to pick the most useful variables than to focus on the technology per se. To make a substantial impact on the program, it is advised to focus on the variables that are simple enough to be understood and, in turn, used by all practitioners at the club (ranging from the coach to players) and are valid and reliable enough to be trusted when decisions have to be made. When it comes to describing the different types of tracking variables available on the market, the classification of Gray\textsuperscript{2} stands out. He uses 3 distinct levels:

- **Level 1**: Typical distances covered in different velocity zones (“old school” type of analysis, provided by all technologies). Example: 345 m run above 19.8 km/h.
- **Level 2**: All events related to changes in velocity—accelerations, decelerations, and changes of directions (provided with more or less success by all technologies). Example: 45 accelerations over 3 m/s\textsuperscript{2}, for a total distance of 233 m.
- **Level 3**: All events derived from the inertial sensors/accelerometers (microtechnology only, so unavailable with camera-derived systems). Examples: 17 impacts above 6 g, PlayerLoad of 456 AU, stride variables (force load on the ground, contact times), stride imbalances (4% reduced impulse force on the right leg).\textsuperscript{8,9}

In a recent meta-analysis,\textsuperscript{1} total distance, high-speed running, acceleration/deceleration patterns, and metabolic power were the variables that were rated as the most important for elite team practitioners. Total distance is generally used as a proxy of overall training volume. High-speed-running distance (also called stride work, which involves high activation of hamstring muscles) and acceleration/deceleration patterns (also called mechanical work, involving tight muscles) are believed to be the most important variables to be tracked since they refer to a more neuromuscular-oriented type of load, which is likely more linked with injury risk.\textsuperscript{3,10,11} Metabolic power is a hybrid measure based on both level 1 and level 2 types of variables and is meant to provide a good estimate of the overall cost of high-intensity actions while combining the actual cost of high-speed (level 1) and accelerated (level 2) running.\textsuperscript{12} Unfortunately, however, practitioners are left with a difficult dilemma when selecting their variables, since their validity and reliability is likely inversely related to their importance in terms of load monitoring, that is, high-speed running, acceleration/deceleration work, and metabolic power being the least valid and reliable variables.\textsuperscript{1,13} In other words, the variables that are believed to be best are likely the least useful.\textsuperscript{2} This does not mean that those variables should not be monitored but, rather, suggests that greater care should be taken when interpreting their differences or changes (ie, defining a larger, more conservative smallest worthwhile difference/change).\textsuperscript{14} Also, a variable with a

**Tracking Accelerations and High-Speed Running: Time to Slow Down?**

**Which Variable to Choose?**

Figure 1 — Distance covered above 14.4 km/h during a typical week by a representative academy player in an elite French soccer club. During this specific week, he was tracked using both the academy and 1st Team GPS systems and by a semiautomatic camera system during the match he played with the Pros. Left columns represent raw (as collected) data (total = 4693 m). Right columns represent the actual distance estimated via calibration equations that could have been expected to be measured if he had worn consistently the 1st Team GPS system (total = 4558 m). Note that while the academy system tends to provide lower estimates than the 1st Team system, the semiautomatic camera system provides greater values. Finally, based on historical drill data,\textsuperscript{3} 50 m above 14.4 km/h have been added manually for the recovery session (light stride work).
Limited validity can still be useful if it is clearly sensitive to training or fatigue (which refers to a large signal-to-noise ratio). It is now very clear that activity patterns of players is more dependent on tactical issues (rules, coaches’ interventions, score line) than influenced by their current fitness status. For this reason, locomotor-related variables (levels 1 and 2) may not be suitable for the monitoring of training status; in contrast, level 3 types of variables can be collected irrespective of players’ activity on the pitch, and have greater potential for the monitoring of fitness and fatigue. It is, however, worth noting that when level 3 variables are not available (using semiautomatic cameras or some GPS brands that do not provide such variables), some relevant information can still be gained with level 1 and level 2 variables—but only in the very specific context of highly standardized drills. Figure 2 shows how a player’s readiness to perform could be assessed during congested fixtures using simple running performance indicators during highly standardized drills, that is, during match-simulation drills the days before matches (in the context of similar small-sided-game formats, number of players, and drill duration). Results show that the longer the between-matches recovery period, the greater the match simulation activity, which mirrors the physiological and performance recovery processes in the 2 to 3 days after matches.

Limitations of Common Tracking Variables, With Special Reference to GPS Systems

In addition to potential validity and reliability issues, there are other important limitations to consider when using some of these tracking variables, including:

- Accelerations values are directly related to the time window (duration over which the acceleration is measured, in general between 0.2 and 0.8 s, Figure 3) and the signal-filtering technique used. There is unfortunately no consensus on the

**Figure 2** — Upper panel: locomotor responses (total distance covered [circles] and mechanical work [triangles] per minute) during match simulation drills (MS) the day before a match (D-1), as a function of the number of days between 2 consecutive matches in professional soccer players from an elite French team. Lower panel: sessions/matches force load (bars) and mechanical work (triangles) as a function of the number of days between 2 consecutive matches. Match simulations: 9 versus 9 players (2 goalkeepers), 50 × 55 m, free touches, 2 × 8 minutes. Mechanical work is a variable provided by the ADI analyzer as a compound measure of accelerations, decelerations, and changes of directions.
optimal time window and filter to use. A simple and relevant alternative to the use of arbitrary time windows could be to report acceleration over a meter (ie, the base unit of length in the International System of Units).19

- Companies often update their data processing technique (software or unit chipset updates), which can create large differences in data output.7 It is therefore almost impossible to hold historical databases, unless you never update your system.

- The number of GPS satellites available and their spread in the sky (geometric dilution of precision (GDOP), with the greater the spread of the satellites, the better the signal quality) in response to variations in time of day, location on earth or possible infrastructures (stadium roofs may cause partial blockage); unfortunately, however, activity reports do not readily provide this detailed information, leading to a potentially unclear representation in their readings.

- There are large differences in GPS distance recorded when using the Doppler technique versus local coordinates—while the Doppler tends to be the preferred method today, some inconsistencies remain between brands.

- The validity of accelerations and distance into speed zones is acceleration20 and speed2 dependent; that is, their validity decreases as the acceleration and speed increase. So to speak, variables of most importance are likely the least useful.

- Increased sampling frequency does not always translate into better precision and validity.5

• There are large between-units variations (up to 50%), even between units from the same brands.7 The direct consequence is that players should always use the same unit, and we should always remain cautious when comparing different players’ data (and use larger magnitude thresholds for meaningful differences14).

**Metabolic Power: Powerful Enough to Drive Ferraris?**

Since Osgnach et al in 201012 showed the potential application of the metabolic-power concept21 for load monitoring in soccer, the interest for this variable has grown exponentially and is now used across many other team sports.22–25 In fact, most GPS brands now offer the ability to monitor players’ metabolic power, and a majority of practitioners use this variable when reporting.1 While we26 have been the first to be excited about the potential of this monitoring approach, we have since reconsidered our opinion and now question its usefulness in the field to monitor elite players (ie, “Ferraris”). This is essentially related to recent research findings questioning the validity of this construct in the context of team-sport-specific movements and the fact that it is only an incomplete metabolic measure of internal load and a too broad marker of external load.

**What Are We Measuring in the End?**

It has now been shown by 4 distinct and independent research groups that locomotor-related metabolic power assessed via either GPS or local positioning system (PGPS) differs largely from the true metabolic demands as assessed via indirect calorimetry (VO2 measures, PVO2). PGPS was actually reported to be very largely greater than PVO2 during walking27 but very largely lower during shuttle runs at low speed28 and during soccer,26 rugby,29 or team-sport-specific30 circuits. While some may see the consistency of such conclusions as a kind of consensus, Osgnach et al30 suggested that some methodological errors may explain the underestimation of PGPS reported.26–29 Among others, they attributed our discordant results to the inclusion of resting VO2 when calculating PVO2 (while we have in fact used net VO2, as clearly written in Buchheit et al,26 p. 1151, second paragraph), the impact of nonlocomotor actions on PVO2 (while team sports often include intense but static movements that logically increase systemic energy expenditure [PVO2 independently of locomotor movements [PGPS]]31), an underestimation of the anaerobic contribution to PVO2 (while if we had better accounted for the entire anaerobic contribution to PVO2, the PGPS underestimation that we reported would have been even greater, not smaller31), and our 4-Hz GPS sampling frequency (while the other researchers have all reported the same underestimation using higher sampling frequencies ie, 500,28 10,29 and 5 Hz). Note also that we have shown that sampling frequency per se was not the most important factor when it comes to precision and validity.5 Detailed and illustrated answers to these 4 points have been offered elsewhere31 and confirm the limitations of PGPS in the context of interest, ie, monitoring teamsport-specific efforts with the available technology on the market.

**Adding Value to Load-Monitoring Systems?**

Considering that the agreement between PGPS and PVO2 has only been shown to be acceptable during continuous and linear jog and runs (but neither during walking nor intermittent changes of direction runs),27 the metabolic underestimation consistently reported26–29 may be related to the fact that the current equation initially developed for maximal and linear sprint acceleration21 may not be well suited for team-sport-specific running patterns (eg, including
rest, irregular step frequency and stride length, turns, upper body muscle activity, static movements). Additionally, if \( P_{GPS} \) was to only reflect locomotor-related metabolic activity (as opposed to a systemic measure such as \( P_{O_2} \)), what would be the value of such an impartial measure of metabolic load? This is at odds with all attempts to use \( P_{GPS} \) outputs for overall load monitoring or nutritional (posttraining/match recovery) guidelines. Taken together, these limitations suggest that the value of \( P_{GPS} \) per se to monitor training load in team sports may be questionable. Its usefulness may also be limited with respect to practitioners’ expectations in the field. In fact, practitioners are likely seeking

- Overall estimates of internal load, which are in our views satisfactorily assessed through HR and RPE measures—information on the metabolic load of exclusively locomotor-related actions as with \( P_{GPS} \) may not be comprehensive enough.
- Precise measures of external load, which directly relate to specific mechanical constraints on players’ anatomy, which, in turn target specific muscle groups. This has direct implications for training, recovery, and injury risk. However:
  - \( P_{GPS} \) is clearly dissociated from actual muscle activation, as exemplified by very large variations in the \( P_{GPS}/EMG \) ratio during accelerated vs. decelerated running.
  - \( P_{GPS} \), if it was to be used as a global marker of mechanical work (combining level 1 and 2 types of variables), would not decipher the underlying mechanisms of the load—we rather use distance while accelerating, decelerating and while running at high-speed since those variables may relate directly to the load of specific muscle groups.
- Injuries are most generally related to inappropriate volumes of accelerations or high-speed running; there is in contrast little evidence to suggest that spikes in overall energy consumption per se may play a role in injury etiology.

Where Do We Go From Here?

We wished to finish with the introduction of two innovative and promising types of variables (Athletic Data Innovation analyzer [ADI], Sydney, NSW, Australia) not cited in the meta-analysis, that represent clear advances in terms of external load and fatigue monitoring. One of the greatest benefits of these variables is that, in contrast to Level 1 and 2 variables that are pacing- or player-engagement-dependent, players do not need to perform maximally for these latter variables to be useful. From there, every training session becomes an assessment.

- **Force load (FL).** With the ADI analyzer, Force load refers to the sum of estimated ground-reaction forces during all foot impacts, assessed via the accelerometer-derived magnitude vector. In comparison with Player/Body Load (whole-body load based on overall accelerometer activity) or total distance, FL reflects only locomotor-related impacts and provides better estimates of overall foot work and impulses, especially when the sessions include static movements and little displacements (eg, toros, football tennis, free kicks).

  a. In relation to the actual distance covered (TD/FL) or the average velocity (V/FL) during a given drill, force load can be used for at least 2 purposes: to assess neuromuscular/running efficiency (greater the ratio, better the efficiency) and to provide new insights into the mechanical demands of on-field running drills, such as the main direction of force application (ie, large vs small ratios standing for more horizontal vs more vertical forces applications, respectively, Figure 4). As shown in Figure 4, when comparing for the first time the mechanical demands of different 15-m-sprint conditions, the V/FL ratio decreases with the increased need for horizontal-force production.

  b. Force load can also be compared between right and left legs, and stride imbalance can be tracked during any type of locomotive actions (eg, specifically while accelerating vs running at high speed, which likely relates to the use and potential weaknesses of different muscle groups). This is obviously very relevant during the return-to-play period (Figure 5) and to track eventual muscle-strength deficits in yet healthy players.

![Figure 4](image-url)
Stride characteristics (contact and flight time, also calculated from accelerometer data). From these simple variables it is now possible to accurately calculate vertical stiffness, which has been shown to decrease substantially with neuromuscular fatigue. The constant monitoring of stride characteristics (or at least ground impact-related lower-leg vertical activity), more preferably during standardized running bouts, offers a new alternative to the V:FL ratio and provides new perspectives for the field monitoring of neuromuscular status. Another very practical aspect of the present stride variables is that accelerometers can be used indoor (ie, no GPS signal needed), allowing their use for almost every type of running-based sports (eg, basketball, handball).

Conclusion

Monitoring players’ overall external training load is only possible through the integration of the different technologies used in combination in most clubs (eg, GPS and semiautomatic camera tracking for training and matches, respectively). Until new solutions are developed, the use of club-specific calibration equations is probably the “lesser of all evils,” but practitioners would still be faced with the downside of technology and/or computing advances (eg, firmware or software updates), which ultimately compromises long-term monitoring plans. When it comes to monitoring training status, level 1 and 2 tracking data may only be worthy in the context of highly standardized drills. In contrast, pacing-free level 3 variables (eg, stride parameters, force load) may offer a greater sensitivity, although more research is still warranted to confirm this hypothesis. Considering that the perfect tracking system still does not exist, and given the numerous limitations of the most advocated variables (accelerations, metabolic power), the foundations of a successful player-monitoring system should focus on the manner in which practitioners collect their own tracking data, their understanding of the limitations of each variable, and how they report and use all this information, rather than in the technology and the variables per se. Furthermore, the validity and reliability of the practical interpretation of tracking variables should never be overlooked; the most useful tracking variables are very likely those that can be understood and in turn, used by all practitioners at the club. Our opinion is that before adopting new pieces of technology or variables, practitioners should assess their usefulness first, to ensure worthwhile incorporation into their program. Overall, the decision to use any tracking technology or new innovative variable should always be considered with a cost/benefit approach (ie, cost, ease of use, portability, and manpower/ability to affect the training program). Technology should be preferred over simpler methods only when unique and important information can be obtained (eg, the percentage of maximal speed reached during a session, which may directly affect injury risk, cannot be assessed via session RPE). Anecdotally, very successful coaches still make most of their decisions based on information as simple as accumulated training and playing time! We are nevertheless confident that in the future, with the advances in terms of micro technology, the development of new tracking variables and appropriate sport-science support, even those coaches would start to see the glass as half full.
